ABSTRACT

A study was made of the burning characteristics of some 140 different materials for the purpose of obtaining technical data and criteria needed to support current efforts to improve existing Federal Air Regulations governing the use of cabin interior materials in aviation.

Comparative tests were conducted on two groups of materials; one consisting of materials now in use in air transport, and the second materials proposed for future use with superior fire resistance. Measurements were made of ignition time, burn and char lengths, flame-out time, burn rate, heat of combustion, flame-spread index, etc. Two standard laboratory test methods were employed; namely, (1) Federal Standard CCC-T-191b, Test Method 5902, Vertical Burning Apparatus, and (2) Federal Standard 00136b (ASTM E-162), Radiant Panel Apparatus.

Results of the tests were analyzed to indicate major flammability trends for different material classifications. Practical allowable flammability limits based on available materials technology were recommended for increasing the present fire protection requirements of interior materials.

INTRODUCTION

Purpose

The test program covered by this report is part of a continuing project effort first initiated in 1963 to investigate possible fire, smoke, and toxic gas hazards resulting from the use of combustible interior cabin furnishings and construction materials. This particular phase of the project was concerned primarily with a study of the flammability and burning characteristics of individual materials by means of standard laboratory test methods and procedures. Fire tests were conducted on two large groups of materials for comparison in performance. The first group consisted of materials typical of those in current use in aviation, while the second group consisted primarily of newer or experimental materials that are more representative of the current state of the art of materials technology.

The findings presented in the report were intended to provide background information and criteria needed to support current efforts by the Federal Aviation Administration (FAA) in cooperation with the aviation industry to improve and update regulations governing the use of safer cabin interior materials in aircraft as part of general revisions of the Crashworthiness and Passenger Evacuation Standards - Transport Category Airplanes. Specific goals of the program were to establish appropriate test methods and set realistic flammability limits covering the entire range of cabin interior materials.

Background

Since much of the interior construction and furnishings of airplane cabins are not only combustible but also are contained within the same close environment with passengers, the presence of a fire condition may be suspected of sufficient severity to cause some concern over safety. It is understandable that the major emphasis on fire protection in the past would have been associated with fear of ignition of the large quantities of highly flammable fuels carried aboard aircraft. Major fires involving cabin interior materials would normally be expected to originate outside the cabin from a fuel fire spreading through the interior materials from an opening or break in the fuselage following a crash landing and fuel spill fire accident. In comparison, only minor significance was attached to any possibility of severe fires originating entirely within the cabin materials proper. Notwithstanding this low incident appraisal, regulations had been adopted to limit the degree of flammability of interior materials to controllable levels by requiring the use of materials designated as flame-resistant or slow burning. Regulations establishing minimum standards for these materials were contained in an early Flight Standards Service Release No. 259, dated August 26, 1947. The document established a maximum horizontal burn rate of 4 inches per minute for showing compliance with the regulations. Despite recent amendments this past year, the above burn rate remains in effect for some materials (Reference 1).

Interest in the burning characteristics of interior materials has accelerated since 1960 with the occurrence of a series of major cabin fires in parked jet transports (Reference 2). Losses from such sporadic fires have been so severe as to encourage some airlines to provide their overhaul bases with rapid means of inerting unoccupied cabins with an extinguishing foam agent in case of internal fire (Reference 3). As a result of past fire experience and the implied threat to passenger safety, both Government and major airplane companies in recent years have embarked on extensive test programs to investigate the combustible characteristics of materials by utilizing standard laboratory tests (References 4, 5, 6, and 7). Supplementing evaluation tests on separate materials, full-scale cabin fire tests were conducted on completely furnished transport cabins to obtain a better understanding of the nature and extent of the hazards to which passengers may be exposed (References 8 and 9). This earlier work has been greatly expanded during the past 2 years to include other phases of the general problems that pertain to control and extinguishment of post-crash or inflight cabin fires (References 10 and 11).

Much of the impetus for the present increase in cabin fire research and materials investigation designed to improve existing regulations developed as an aftermath of the Boeing 727 crash landing and resulting fire at Salt Lake City in November 1965. Experience gained from a study of this accident opened up other areas of interest in fire protection such as the smoke and toxic hazards which accompany fire (References 12 and 13). This has led to a cooperative project effort with the Fire Research Section of the National Bureau of Standards to study and measure the smoke and toxic characteristics of burning interior materials. The results of this work will be the subject of a separate report (Reference 14).

DISCUSSION

Fire Testing

Aviation safety, following a survivable crash landing accident, may be largely dependent on the ability of materials to resist and contain the effects of fire. Federal Aviation Regulations Part 25 - Airworthiness Standards for Fire Protection, specify four separate materials categories depending upon their intended use or location in the aircraft. In order of decreasing severity of application, these are listed as follows: (1) fireproof, (2) fire-resistant, (3) flame-resistant, and (4) flash-resistant. The first two categories are for materials either completely or largely noncombustible in composition. Materials so classified are required to show resistance to flame penetration from either the standard 2000°F - 2.0 gph kerosene torch or a Bunsen burner. Materials in this group include metals, glass and asbestos, used either separately or in combination with some organic binder, as with certain fire-resistant composites. In contrast, flame- and flash-resistant materials are primarily organic in composition and, therefore, basically combustible. The maximum burn rate permitted under present Federal Regulation, adopted in 1947 for rating materials designated as flame-resistant, has remained at 4 inches per minute as tested in the horizontal position. This regulation has made possible the use of a wide selection of plastics which proved to be well suited to meet the demands of modern air travel for both cabin comfort and decor. However, subsequent tests on a large selection of cabin interior materials had shown that, for the majority of such materials, the above burn rate figure was too lenient. With the exception of certain types of materials, notably seat upholstery and foam padding, most materials were found to be self-extinguishing with a zero horizontal burn rate. Lately, in response to the greater awareness of cabin fire dangers and also to take full advantage of the latest developments of materials technology, a goal was set that would require that all interior materials eventually be self-extinguishing (Reference 15). This has already resulted in a recent revision to the Federal Standards requiring that certain types of interior materials used mainly for wall, ceiling, partition, and floor construction be self-extinguishing in the vertical position within an 8-inch char length (Reference 1). The improved regulations are intended to reflect gains in fire resistance from the present state-of-the-art materials technology. The revised standards have also eliminated the lowest category of flash-resistant materials which permitted a burn rate as high as 20 inches per minute for materials such as seat padding.

Choice of any one particular fire test method generally accepted as valid for rating all materials is complicated by the extreme range and complexity of cabin materials in relation to composition and form. For example, interior materials may range from light weight fabrics and films only a few thousandths of an inch thick to seat padding and complicated

honeycomb assemblies with thicknesses of 1 to 4 inches. Many different test methods, depending on the particular type of material and severity of application, have been devised and sponsored by both Government agencies and technical societies. Standards issued by these organizations frequently specify the same method under different designations. An example of such universality is Test Method 5902 for measuring char length under such various designations as: ASTM 626-55T, NFPA Standard No. 701, AATCC Standard 34-1952, MIL-C-20696, MIL-C-7514B (ASG), CCC-A-680a, Standard 3119 (England), DIN 53906 (Germany), etc. Since it is virtually impossible to equate the severity of one test method with that of another for comparison, it becomes necessary, if possible, to select a single method that will best evaluate and cover the entire range of cabin materials regardless of type or use. This was in accordance with past regulations which specified the use of only one common test method for all materials designated as flame-resistant. It should be noted that although this test method had been designed originally for measuring the burn rate of fabrics, it was applied equally to all cabin materials without distinction.

Major factors related to fire which may provide useful data for a materials rating system are as follows: (1) minimum heat, temperature and time required for ignition, (2) rapidity by which flames propagate following ignition, (3) tendency for flash fire to suddenly erupt, (4) tendency for flaming to become self-extinguishing upon removal of the ignition source, and (5) rate and total heat generated by the combustion process. Other factors of increasing interest to aviation safety are measurements of smoke and other combustion product concentrations as these affect either visibility or indicate a toxic hazard.

The single most significant factor listed above in considering improved standards is that of the ability of the material to become self-extinguishing within both a short char length and rapid flame-out time following removal of the ignition source. Laboratory tests utilizing a small ignition source such as a Bunsen burner flame on which present regulations are based have been supplemented with other test methods utilizing a much larger source of heat including radiant and convective which would be more representative of an actual cabin fire environment. Materials at elevated temperatures are known to be much more flammable than that indicated by the Bunsen burner tests under normal ambient temperature conditions typical of an incipient fire. A test method of the more severe type most widely recognized by the building fire codes specifies a gas-fired, 25-foot long tunnel for rating materials (Reference 16). The radiant panel test method (Reference 17) used in this investigation was designed to simulate the severity of the tunnel and provide more conveniently the same type of flame-spread index data. In addition to the comparative laboratory tests on individual materials, it is desirable that materials be evaluated on location under conditions typical of full-scale fire. The results of such tests will be contained in separate reports to be presented at a later date.

Materials Description

A total of nearly 150 materials designated as cabin interior materials and listed in Table I of the appendix were investigated for their flammability and burning characteristics. For purposes of analysis and comparison, the materials were divided into five main classifications based on use and physical structure: (1) fabrics, (2) rugs, (3) sheets, (4) laminates, and (5) assemblies. For better identification, each of the above classifications were subdivided as follows: (1) coated and uncoated for the fabrics, (2) padded or unpadded for the rugs, and (3) rigid, semirigid or flexible for the sheets and laminates.

Materials numbered below 100 are listed as Group I in the table containing 76 materials. These were obtained from four different suppliers consisting of two major commercial airplane companies, one airline, and one seat manufacturer. As such, the list should constitute a representative cross section of materials in current use in air transports. Materials numbered above 100 are listed as Group II containing 65 materials. These were obtained directly from materials manufacturers including most of the major chemical companies among the total of 24 different suppliers. For purposes of this test program, the latter group of materials were considered experimental and representative for the most part of recently developed materials with superior fire resistance.

The chemical compositions listed for the materials were obtained by the National Bureau of Standards by utilizing mainly infrared spectrophotometer techniques supplemented by manufacturers' data when available. The most striking feature in the compilation of the data in Table I is the extreme variation between different materials not only in physical properties but also in chemical composition. Almost all of the materials were composed either entirely or in part of organics and were thus combustible to some degree. Most of these organics were synthetic in origin.

The most typical plastics encountered in the analysis of the materials were the vinyls, acrylics, and acrylonitrile/butadiene/styrenes (ABS). Of special interest were the more recently developed high temperature polymers: namely, aromatic polyamide, polyimide, polycarbonate, polysulfone and the fluorocarbons (References 18 and 19). Also, Group II, consisting of the newer and more fire-resistant materials, is distinguished from the first group by the greater use of noncombustibles in the construction of the materials.

Equipment Description

Vertical Flammability Test Method Apparatus: This apparatus is used in Federal Specification CCC-T-191b, Method 5902 (and 5903T), and is shown by photograph in Figure 1. The essential parts of the apparatus consist of a Bunsen burner ignition source, a ventilated metal cabinet to provide a draft-free environment, a rigid specimen holder to assure rigid specimen support, a set of weights and a timer. The Bunsen burner was fed from a tank of compressed synthetic gas of known composition (H_2 - 55%, CH_4 - 24%, CO - 18%, C_2H_6 - 3%) and heat content of 540 Btu per cubic foot at standard atmospheric conditions. Method 5903T differs from Method 5902 only in that the composition of the gas is specified, instead of being optional, and as such represents the latest revision to the basic test method.

Radiant Panel Flame-Spread Method Apparatus: This apparatus is used in Federal Standard No. 00136b (ASTM E-162) and is shown by photograph in Figure 2. The essential parts of the apparatus consist of a gas-fired porous refractory panel heat source, an acetylene pilot torch ignition source, a specimen holder, a temperature instrumented stack, and a timer. A brief description of the major parts of the apparatus follows:

Radiant Panel - This provides a radiant heat source environment to the burning test specimen. The panel consists of a porous refractory ceramic surface fed from the rear with a premixed propane/air supply. Combustion is nearly completed within the pores of the ceramic panel providing a uniform black body glow temperature of $1238^{\circ}F$ over the entire panel area measuring 18 by 12 inches. A radiation pyrometer shown in the photograph is used to adjust the correct operating temperature of the panel.

Pilot Burner - This provides a flame to force ignition at the top of the specimen. The burner consists of a short length of 1/8-inch I.D. stainless steel tube with a porcelain nozzle attachment. The burner is fed with acetylene premixed with air and the flame adjusted to a length of 2 to 3 inches.

Specimen Holder - This provides a rigid support for the test specimens and consists of a frame with a clamping arrangement. Overall size of the holder is 19-3/8 by 6-1/4 inches, allowing an exposed surface of 17-5/8 by 5-1/4 inches. The holder is inclined at an angle of 30 degrees away from the radiant panel which is in a vertical position. This method of mounting assures a graduated heat flux from top to bottom of the test specimen in the ratio of about 10 to 1 with a maximum value of about $3.0 \text{ Btu}/\text{ft}^2/\text{sec}$. Markings on the holder at 3-inch intervals are provided for timing flame propagation.

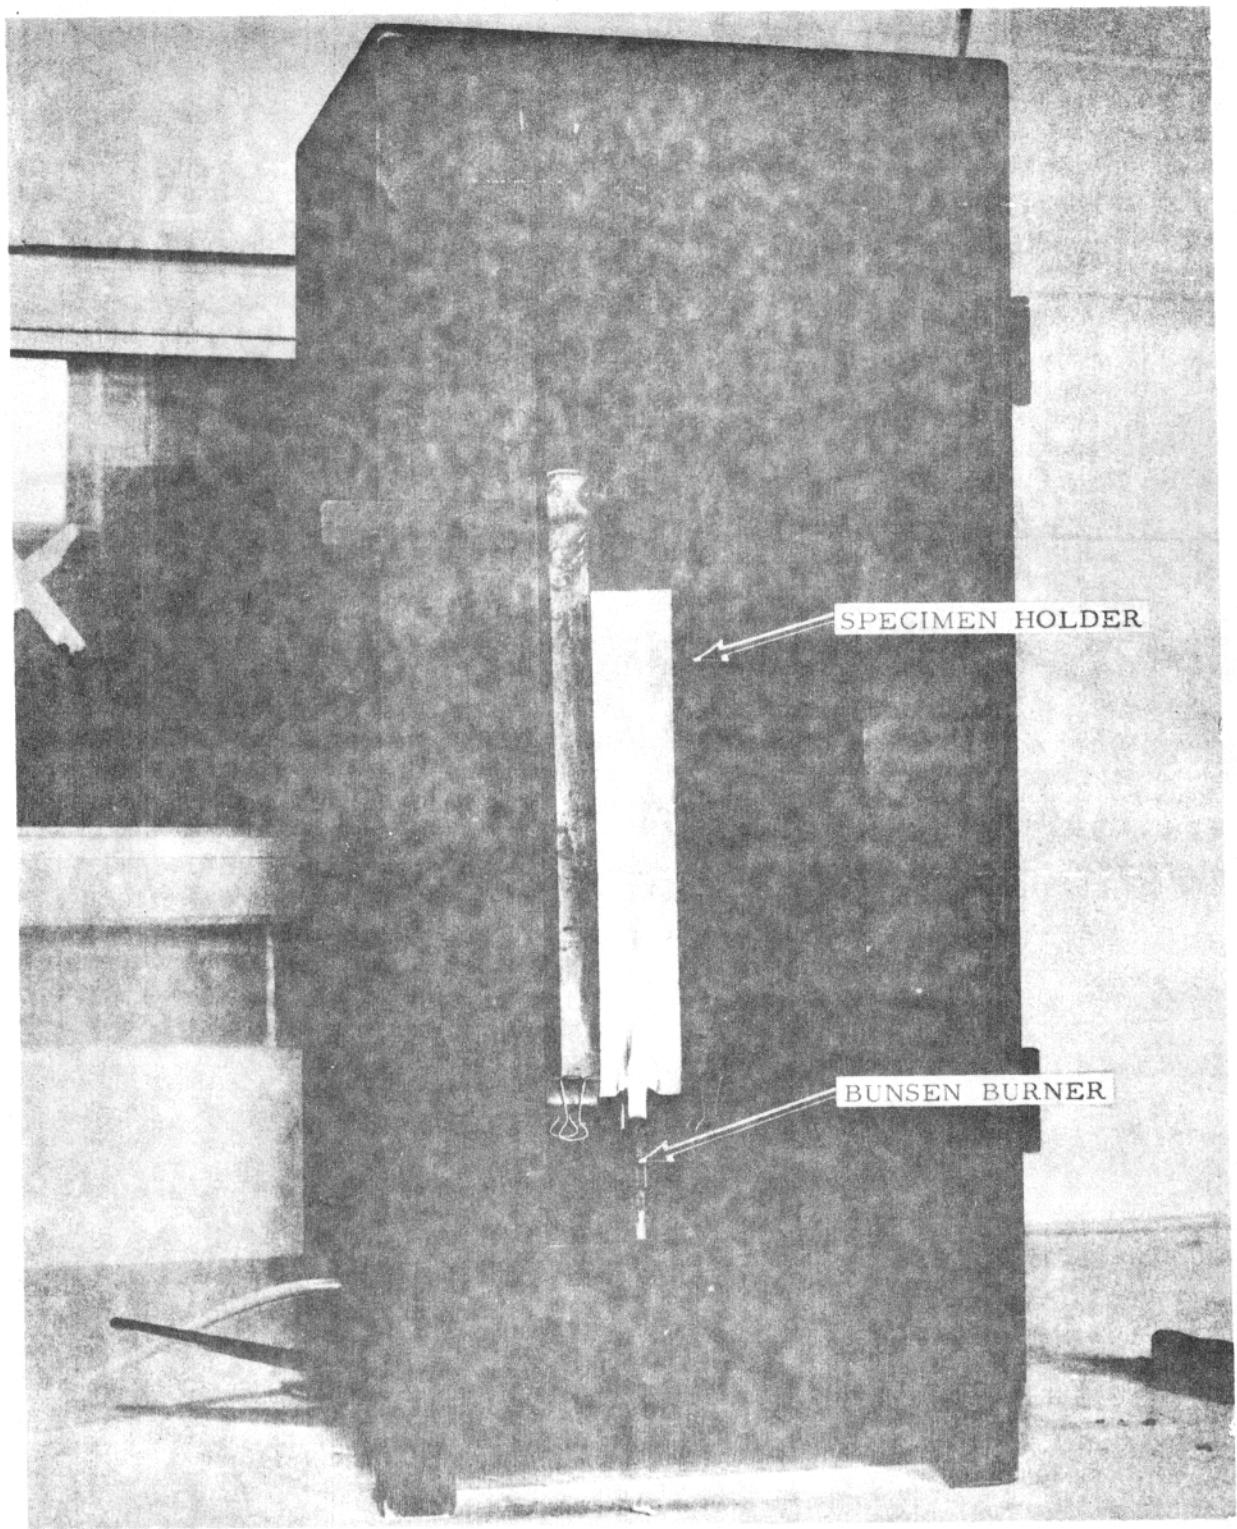

FIG. 1 VERTICAL BURNING TEST APPARATUS

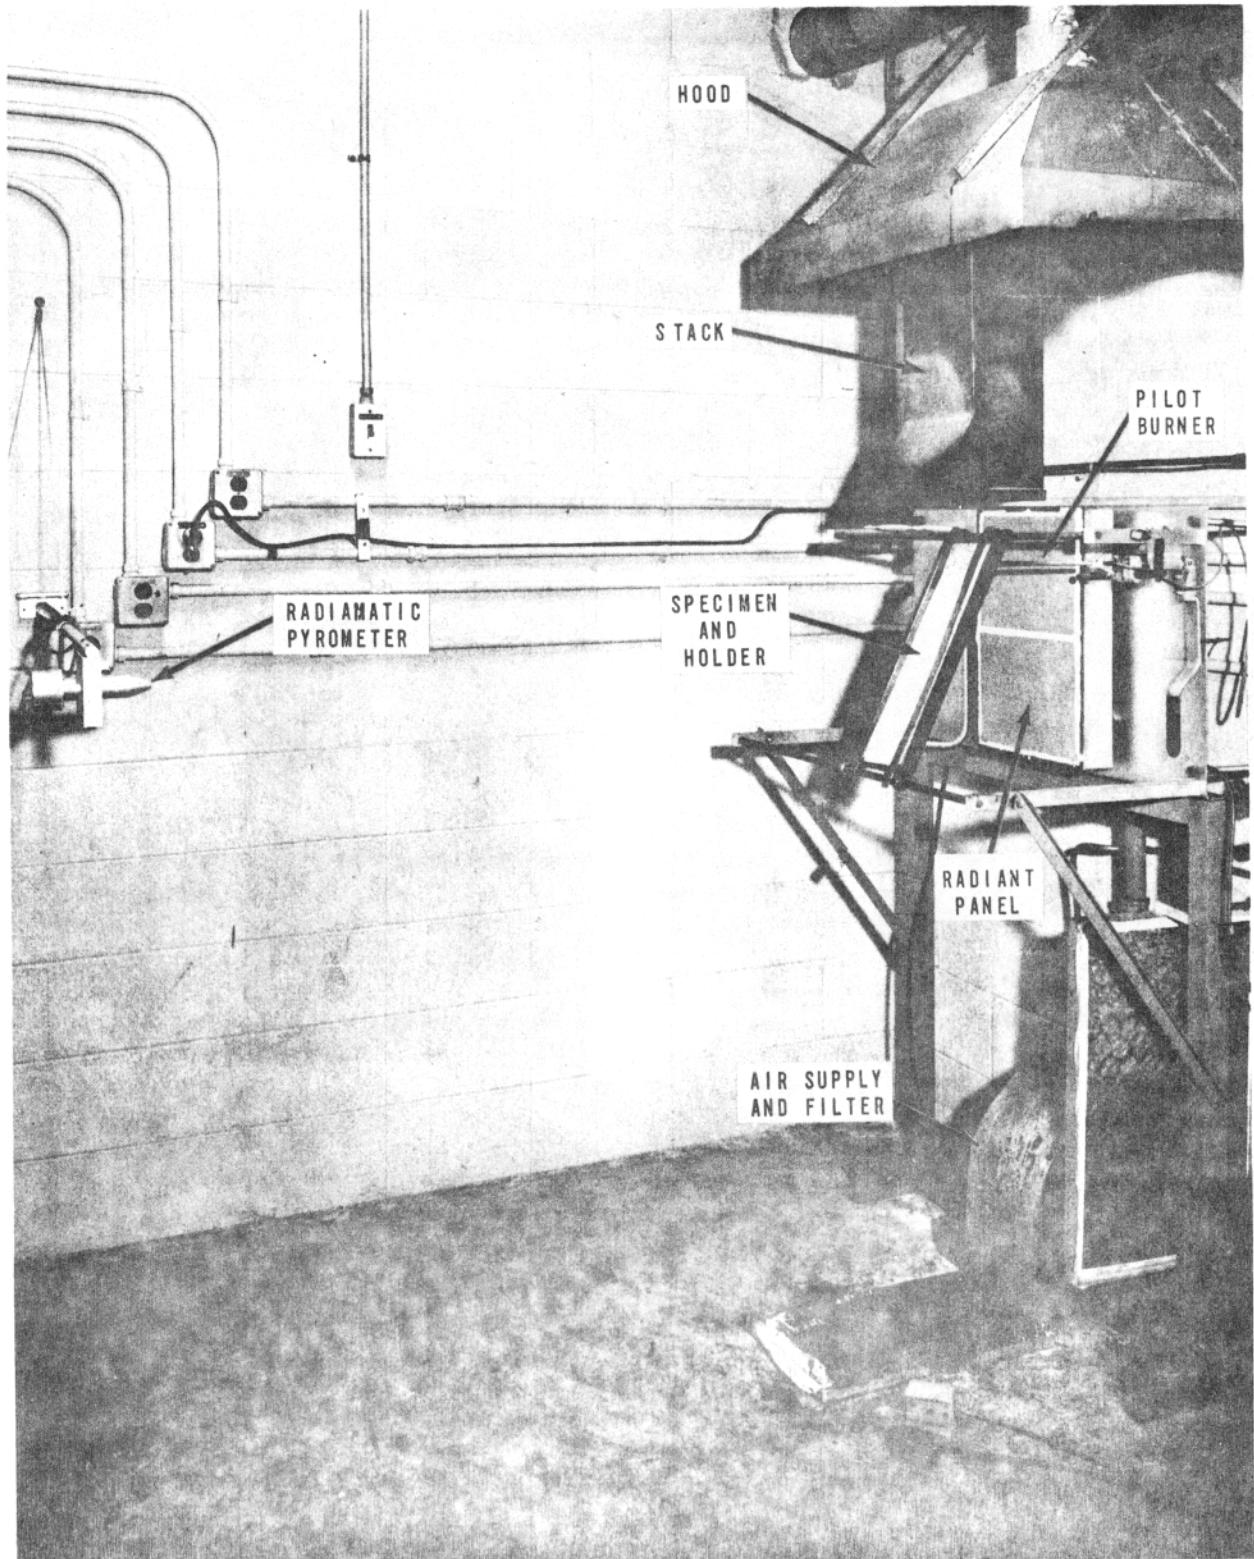

FIG. 2 RADIANT PANEL FLAME-SPREAD TEST APPARATUS

Instrumented Stack - This provides the means for measuring the heat rise in the exhaust stack caused by the combustion of the test specimen. Eight chromel-alumel thermocouples connected in parallel are placed in the stack to provide an average air temperature which is recorded continuously during the entire test. Airflow through the stack is provided by a centrifugal blower rated at an initial minimum velocity of 100 feet per minute (250 feet per minute hot).

Laboratory Tests and Measurements

Vertical Flammability Test Procedure:

1. Three specimens, 12 by 3 inches, were cut from the same sample material lengthwise to the most critical burning dimension.

2. The specimens then were placed in a conditioning chamber for at least 12 hours set at a relative humidity of 50 percent and a temperature of 70°F.

3. One specimen at a time was removed from the conditioning chamber, clamped in the holder, placed inside the cabinet, and hung vertically from a horizontal bar. The specimen was positioned so that its edge was three-fourths of an inch directly above the center of the burner barrel. The burner was adjusted to a height of 1-1/2 inches with no premixed air and then slid into position by means of the handle attached to the burner to start the test. The specimen was exposed to the burner flame for 12 seconds only.

4. Ignition time was measured from the instant the burner was placed under the specimen until the time the specimen began to flame or until a definite change was observed in the size and color of the burner flame.

5. Total flaming time was measured from the instant flaming was observed until the time that flaming ceased.

6. Flame-out time or flame time was measured from the instant the burner flame was removed until the time flaming of the material ceased.

Materials which flamed out before the burner was removed are shown in the data with minus (-) readings to indicate this event. Flame-out time is one of the most important measurements specified by this particular test method, the other being char length.

7. Glow time was measured from the instant flaming stopped until the time the specimen ceased to emit light.

8. Burn length was measured as the total length of the specimen exhibiting some physical change resulting in structural damage or color change apparent to the eye. In the case of the more flammable materials with a well defined flame front, burn length may be measured visually by observing the maximum distance of flame propagation. Specimens which did not burn completely (less than 12 inches) were classified in the test data as self-extinguishing while complete burning was denoted by an X.

9. Char length was measured as the total length of the specimen exhibiting essentially total destruction of some portion of the body or surface area of the material as evidenced by melting or carbon formation. A pointed probe similar to a ball point pen was used to dig into the carbonized surface to determine the limits of char formation. Char length as determined above would always be shorter than burn length since it represents the more heavily damaged part of the material.

For uncoated fabrics, char length was measured in accordance with standard procedures by measuring the total tear length obtained by supporting a known weight by one edge of the damaged specimen as specified by the test method. For coated fabrics with glass, asbestos, or metal backing which resisted fire, char length was measured over the surface area of the organic coating which was completely destroyed. It should be recognized that for many of the materials, char measurement could be influenced by personal choice. Thus, a more liberal measurement of char length by one experimenter could approach that of the corresponding burn length by another.

10. Maximum flame height was measured as the maximum height of the flame observed during the entire duration of the test. The ceiling height of the chamber limited the measurements of the more flammable materials as indicated in the test data.

11. Burn rate was calculated by dividing the burn length by the total flaming time including the 12-second burner exposure time.

12. Smoke, odor and other burning characteristics of the specimen were noted and recorded.

Radiant Panel Flame-Spread Test Procedure:

1. Three specimens, 18 by 6 inches, were cut from the sample material lengthwise to the most critical burning dimension.

2. The specimens prior to fire testing were conditioned as in Test Method 5903T.

3. A calibration of the apparatus was made to determine proper operating temperatures and airflow.

4. The specimen covered by a 1-inch mesh poultry netting for mechanical support was next placed in the holder. A 1/2-inch thick asbestos millboard was then placed in the holder for backing up the specimen with a 1/2-inch air gap separating the specimen from the millboard.

5. The pilot burner was ignited and adjusted to proper length and intensity.

6. The specimen holder was next placed into position with the pilot flame to initiate the fire test.

7. Ignition time was measured from the instant the specimen was placed in contact with the pilot flame until the time flaming of the specimen was observed. For materials that did not show a definite flame pattern, ignition time was measured by noting the occurrence of an increase in the size of the pilot flame or change of color.

8. Total flaming time was measured for the periods of time when flaming of the specimen was visible to the eye.

9. Maximum flame propagation was measured by observing the farthest penetration of flame down the length of the specimen, as noted against the scale engraved on the side of the holder. Flaming extending beyond the 15-inch mark was indicated by an "X" to denote that it was not self-extinguishing.

10. Glow time was measured from the instant open flaming stopped until the time the specimen ceased to emit light.

11. Total burning time or test duration was measured from the instant the specimen was placed in front of the radiant panel until the time the specimen was removed at the end of the test. The test was terminated when flame propagation reached a distance of 15 inches or, failing this, when complete charring of the specimen became evident. Low flammable materials were exposed to the radiant panel for a total exposure of 15 minutes before termination of the test.

12. Char length was measured as in Test Method 5903T and represented essentially total destruction of the surface of the specimen. Because of severe exposure to an external radiant heat source, materials exhibited considerable charring even in the absence of open flaming by the test specimen contrary to the experience with Test Method 5903T.

13. Total heat contributed during the total burning time was calculated from the area under the stack temperature-time curve multiplied by the radiant panel calibration factor.

14. Maximum temperature rise was measured from the peak stack temperature recorded above a baseline temperature for a totally noncombustible specimen.

15. Flame-spread factor (F_s) was calculated from flame propagation data for 3-inch increments of distance along the specimen length.

16. Flame-spread index (I_s) was calculated from the product of the flame-spread factor, the maximum rise in stack temperature and a calibration factor as shown by formulas contained in Federal Standard No. 00136b. The index scale is based on a zero rating for an asbestos/cement panel and 100 as a representative value for untreated wood test specimens. Thereby, a direct numerical comparison is provided for flammability rating over a wide range.

17. Coefficient of variation for flame-spread indices was calculated by standard statistical methods.

18. Smoke, odor and other burning characteristics of the specimen were noted and recorded.

SUMMARY OF RESULTS

Vertical Flammability Tests

Materials investigated are described in Table I of the appendix. The extensive laboratory test data obtained for the materials are contained in Table II of the appendix. A summary of these data is presented in Tables I and II and Figures 3 and 4 of the text for greater convenience in interpreting and comparing the various test results for different materials.

A total of 134 different materials was tested. These were divided into two major groups with Group I comprising materials typical of current usage and Group II comprising materials considered new or experimental. The flammability ratings for each group are highlighted by the following general statistical figures:

Group I - Materials Nos. 1 - 76 of which:

<u>56</u> were self-extinguishing and did not burn completely	<u>78% of total</u>
<u>53</u> were self-extinguishing within a char length of 6 inches	<u>74% of total</u>
<u>20</u> were self-extinguishing within a char length of 1 inch	<u>28% of total</u>
<u>47</u> were self-extinguishing within a char length of 12 inches and a flame-out time of 30 seconds	<u>65% of total</u>
<u>44</u> were self-extinguishing within a char length of 6 inches and a flame-out time of 15 seconds	<u>61% of total</u>
<u>16</u> were not self-extinguishing and burned completely	<u>22% of total</u>

Group II - Materials Nos. 100 - 164 of which:

<u>62</u> were self-extinguishing within a char length of 6 inches	<u>100% of total</u>
<u>47</u> were self-extinguishing within a char length of 3 inches	<u>76% of total</u>
<u>21</u> were self-extinguishing within a char length of 1 inch	<u>34% of total</u>

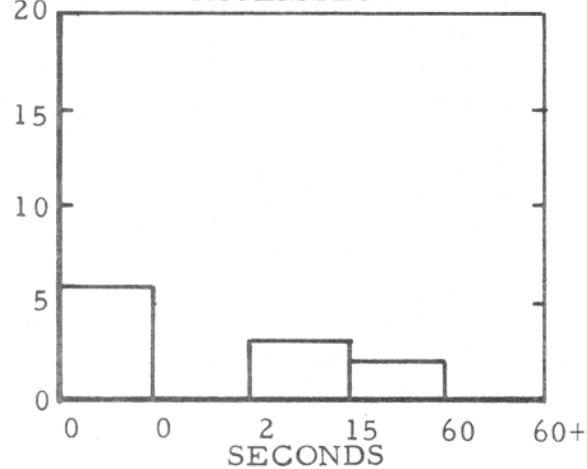

FIG. 4 - FREQUENCY DISTRIBUTION OF FLAME-OUT TIMES BY MATERIAL CLASSIFICATION - TEST METHOD 5903T

<u>59</u> were self-extinguishing within a char length of 6 inches and a flame-out time of 15 seconds	<u>95% of total</u>
<u>55</u> were self-extinguishing within a char length of 6 inches and a flame-out time of 2 seconds	<u>89% of total</u>
<u>19</u> were self-extinguishing within a char length of 1 inch and a flame-out time of 2 seconds.	<u>31% of total</u>

The totals listed above, without consideration regarding particular material type or usage, demonstrated that interior materials were for the most part self-extinguishing. A direct comparison of the figures for the two groups of materials shows the superiority of the second group consisting of the newer materials, many of which incorporate noncombustibles such as glass, asbestos, and metal. Particularly, it should be noted that without exception all materials in Group II were self-extinguishing within the 6-inch char/burn requirement proposed in NPRM 66-26.

A comparison of the flammability data for materials on an individual basis reveals extreme variation to fire exposure as expressed by a burn/char length and a corresponding flame-out time. In general, the thicker and heavier solid materials exhibited the shortest burn/char lengths. In contrast, the materials which burned most completely were the typical upholstery fabrics, rugs, and low density foam materials which have a relatively large surface area to weight ratio. Because of the very limited time that specimens were exposed to the ignition source, the higher weight and more dense materials would be expected to be favored by this test, which was the case. Generally, short burn/char lengths were associated with short flame-out times.

Table II of the appendix contains additional data related to the combustibility of the materials. Ignition of the materials was usually accomplished within 2 seconds. Maximum flame heights were recorded during the fire test in addition to char/burn data. Time during which materials glowed after the flaming ceased was recorded. More than one-third of all materials tested exhibited some degree of glowing with eight materials having a glow time exceeding 15 seconds. Observations were also made of the type of smoke generated during the fire tests as related to quantity, color, and odor. Very heavy smoke was usually observed with the thicker and more flammable plastics. The ABS plastics produced the densest black smoke recorded. The most acrid smoke was produced by the vinyls, especially those that had been apparently chlorinated for greater fire resistance. In addition, peculiar burning characteristics of the materials such as tendency to melt, shrink, form flaming droplets, extinguish the burner flame, etc., were noted.

An analysis of the performance of the materials on the basis of separate classifications follows:

Uncoated Fabrics: Typical upholstery and drapery fabrics of either wool, cotton, nylon, acrylic, or other types of common synthetic construction, alone or blended, were not normally self-extinguishing and burned completely when exposed to the standard vertical test. For some fibers, especially the natural types, chemical additives such as borax and phosphate salts may have been employed to achieve some degree of fire resistance (Reference 20). Out of 10 fabrics in Group I, only one-half were self-extinguishing within the 6-inch char length and 4 of these were constructed of modacrylic fiber which is basically self-extinguishing and has been used for aircraft drapery. All 13 fabrics in Group II were self-extinguishing within the 6-inch char length and of these only 2 did not extinguish in zero flame-out time. In addition to the more common modacrylics, this group included two new types of high temperature aromatic polyamides. The most fire-resistant fabric consisted of an asbestos/glass/organic fiber blend.

Coated Fabric: All fabrics in both groups were found to be self-extinguishing within the 6-inch char length. Except for two cotton backed fabrics, the fabrics exhibited zero flame-out time. Typical materials in this classification were the vinyl and acrylic surface coated glass fabrics.

Rugs: None of the six rugs in the first group constructed of conventional fibers including wool were self-extinguishing. These burned completely with flame-out times exceeding 1 minute. Rugs in the second group constructed of either modacrylic (100 percent) or aromatic polyamide fibers were self-extinguishing within less than 1/2-inch char length and 2-second flame-out time.

Sheets: Out of 27 sheets in the first group, only 7 were found not to be self-extinguishing within the 6-inch char length limit. All these sheets except three had a flame-out time within 2 seconds. The most flammable materials in this classification were the foam seat padding, window transparencies, and ABS panels.

All 30 sheets in the second group met the 6-inch char length criteria and of these only 5 exceeded the 2-second flame-out time. Nearly two-thirds or 14 materials in this group exhibited char lengths of less than 1 inch. Many of these materials were composed of the more typical vinyl, acrylic, and ABS plastics found in Group I containing halogens or various oxides of antimony and phosphorus as fire-retardant additives (References 21 and 22). The most interesting sheet materials tested with superior fire resistance were several new types of high temperature plastics and two fire-retardant foams.

Laminates: All 21 materials in both groups met the 6-inch char length criteria. Only four of the laminates did not extinguish within the 2-second flame-out time. The most fire-resistant materials in this classification were the plastic coated aluminum sheets in addition to the glass and asbestos filled plastics which were outstanding in this respect.

Assemblies: All 10 materials tested met the 6-inch char length criteria and 7 of these assemblies had flame-out times of less than 2 seconds. This classification constituted the thicker and heavier materials and, as such, would not ordinarily be expected to be very flammable by this test method.

Radiant Panel Flammability Tests

The materials investigated are described in Table I of the appendix. Complete test data on the materials are contained in Table III of the appendix. As an aid toward facilitating analysis and comparison of test results for different materials, a summary of the data was prepared which is presented in Tables III and IV and Figure 5 of the text.

Performance characteristics of the two separate groups of materials are highlighted by the following general statistical figures:

Group I - Materials Nos. 1 - 76 of which:

<u>48</u> were self-extinguishing	<u>73% of total</u>
Twenty-four of these materials (one half), however, charred completely from heat exposure to the radiant panel in the absence of open flaming.	
<u>43</u> had a flame-spread index of less than 100	<u>65% of total</u>
<u>26</u> had a flame-spread index of less than 25	<u>40% of total</u>
<u>17</u> had a flame-spread index of less than 10	<u>26% of total</u>
<u>15</u> showed a flame propagation of less than 6 inches	<u>23% of total</u>
<u>18</u> caused a maximum temperature rise of less than 10°C	<u>27% of total</u>

Group II - Materials Nos. 100 - 164 of which:

<u>53</u> were self-extinguishing	<u>90% of total</u>
Twenty-two of these materials (about one-third), however, charred completely from heat exposure to the radiant panel in the absence of open flaming.

ABBREVIATIONS:

F1, F2 = Uncoated and coated fabric; R1, R2 = Unpadded and padded rug;
 S1, S2, S3 = Flexible, semi-rigid and rigid sheet;
 L1, L2, L3 = Flexible, semi-rigid and rigid laminate; A = Assembly.

NOTES:

(1) Self-extinguishing:
 Yes - Neither flames or chars over entire specimen length.
 Yes* - Char but does not flame over entire specimen length.
 No - Flames and chars over entire specimen length.

TABLE IV
DATA SUMMARY FOR RADIANT PANEL TESTS

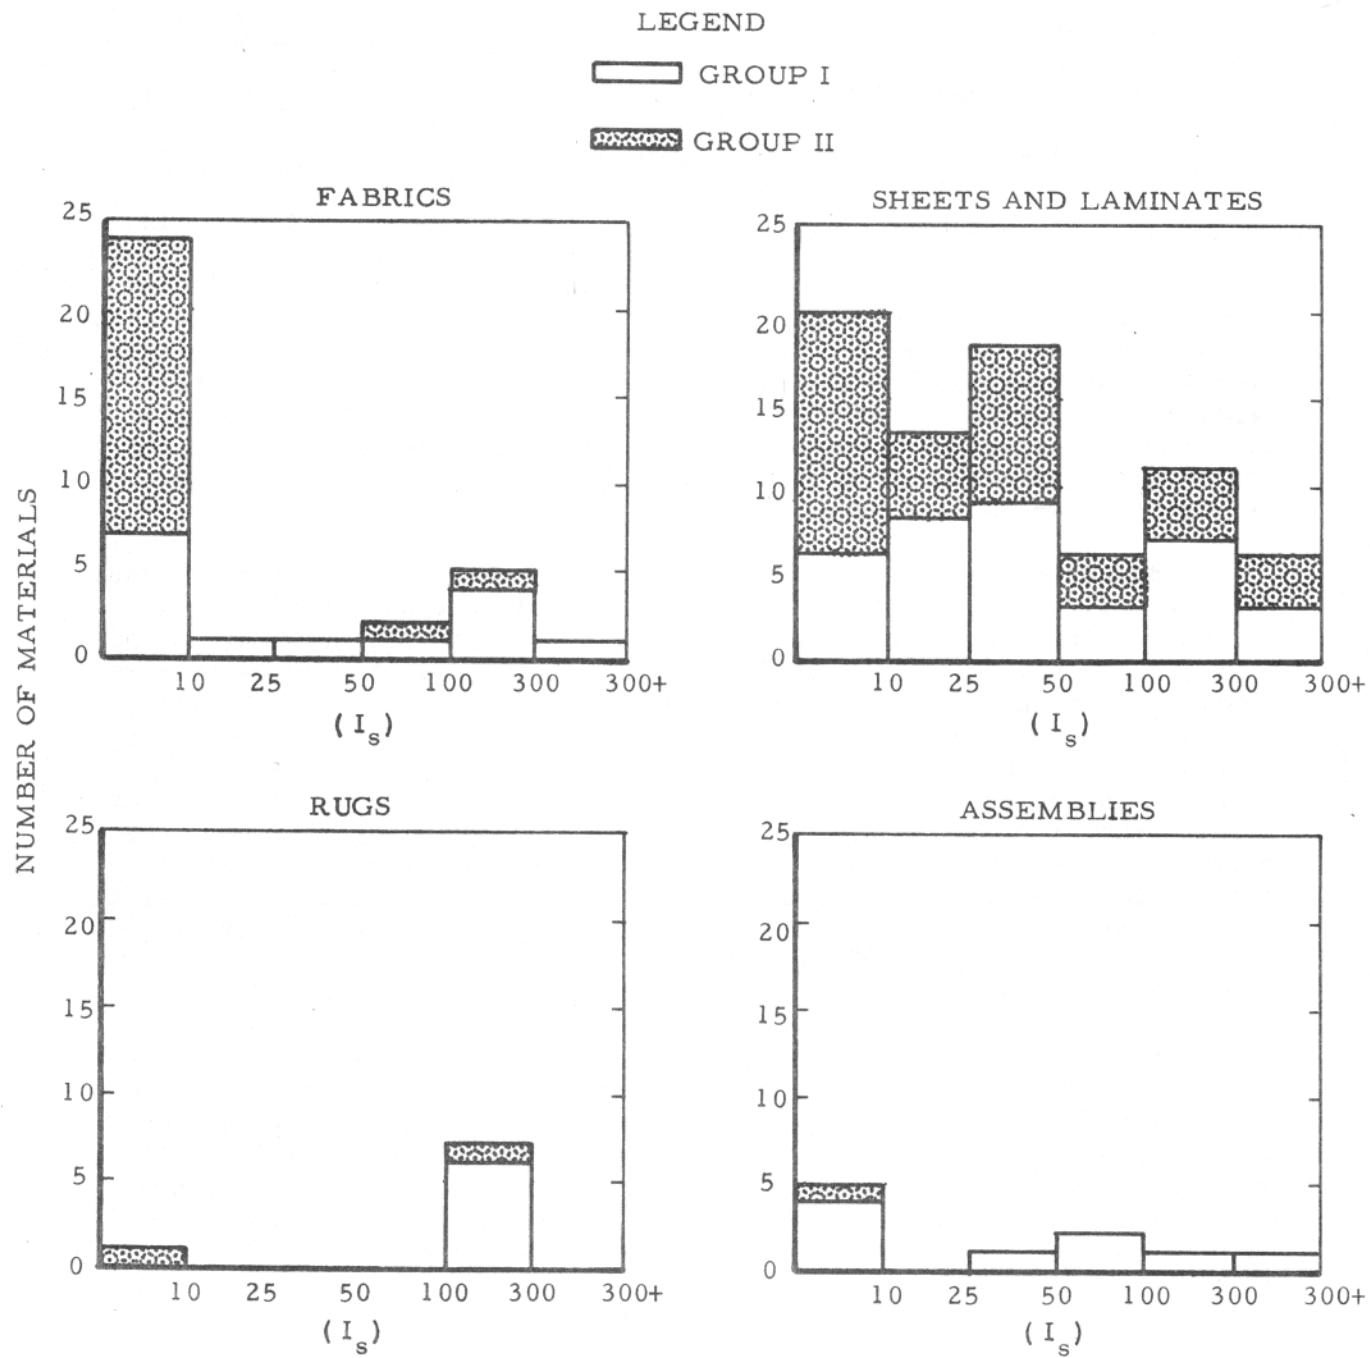

FIG. 5 - FREQUENCY DISTRIBUTION OF FLAME-SPREAD INDEX VALUES BY MATERIAL CLASSIFICATION - RADIANT PANEL TEST

<u>50</u> had a flame-spread index of less than 100	<u>85% of total</u>
<u>38</u> had a flame-spread index of less than 25	<u>64% of total</u>
<u>33</u> had a flame-spread index of less than 10	<u>56% of total</u>
<u>30</u> showed a flame propagation of less than 6 inches	<u>51% of total</u>
<u>24</u> caused a maximum temperature rise of less than 10°C	<u>41% of total</u>

The totals listed above for the materials on a group basis again demonstrated the self-extinguishing characteristics of interior materials. A comparison of the corresponding percentages of total materials meeting various test criteria reveals very definitely the superiority of the second group consisting of the newer materials. Of particular interest, it should be noted that two-thirds of the materials in the second group had a flame-spread index of less than 25 and did not char completely during the 15-minute exposure to the radiant panel.

A comparison of the flammability data for materials on an individual basis shows, as before, a very wide range in flame-spread indices and in the burning characteristics observed. Because of the much more severe environment provided by the radiant panel, it was possible to obtain more complete combustion of the heavier materials which had been relatively insensitive in the vertical tests to exposure of the Bunsen burner. In general, the thinner materials, neglecting the effects of different chemical compositions on flammability, should be expected to exhibit low flame-spread indices because of the low heat factor associated with the burning of these materials. In part, this would be offset by the more rapid flaming of the thinner materials. However, the net effect of using a flame-spread index system tends to favor the minimum use of combustible materials on a weight basis in interior furnishings which would bring about the benefit of increased cabin fire protection.

Table III of the appendix contains additional data related to the combustibility of the materials. Very low index numbers are indicative of superior fire resistance. Ignition of the materials usually occurred within about 5 seconds. Some materials exhibited considerable glowing which was almost always associated with the less combustible materials. Materials with short burning times usually had high flame-spread indices as would be expected. The total heat contributed by the combustion of the materials varied widely with the chemical composition and thickness of the materials. The highest temperatures and Btu readings were recorded for the clear acrylic sheets followed by foam padding. Observations were also made of the individual burning characteristics such as tendency of the materials to flash, melt, drip, etc. Density, color, and odor of smoke produced during the fire tests were observed and recorded. Very heavy black, sooty smoke occurred with many of the ABS sheets. A very acrid smoke usually light in color which frequently snuffed out the acetylene torch was observed with the more fire-resistant

plastics. This effect was associated with hydrochloric acid (HCl) vapor produced from thermal decomposition of chlorinated plastics, especially vinyls.

An analysis of the performance ratings of the materials on the basis of separate classifications follows:

Uncoated Fabrics: The five materials in Group I with an index of 0-10 were modacrylic drapery fabrics. This type of synthetic fiber yielded a low index because of the absence of sustained flaming of the material and the low heat of combustion. Materials with high indices consisted of wool, cotton, nylon, and rayon fibers used for typical seat upholstery. In addition to the modacrylcs, the most promising fabrics in Group II were the aromatic polyamides. These new high temperature polymers not only yielded low indices, but unlike the modacrylics, resisted the charring effect of the radiant panel. Both flaming and heat contribution factors were sufficiently low for this new type of nylon to insure an extremely low index.

Coated Fabrics: In Group I, only three fabrics had indices exceeding 100. Responsible for most of this high index figure were the cotton fabric backing materials. None of the six fabrics in Group II, which as a group were the most fire-resistant of all materials, had an index exceeding 10 or produced a stack temperature rise above 10°C. These materials consisted in large part of the thinly coated acrylic glass fabrics in addition to two types of aluminized asbestos fabrics.

Rugs: A total of eight rugs was tested of which seven had high indices of over 100 and burned completely with high flames and temperatures to make this the most flammable classification. The backing and foam padding of rugs were responsible for much of the flammability of the pile. The only rug which exhibited outstanding fire resistance utilized aromatic polyamide in the construction of the pile. This particular rug had an index of less than 10 and burned less than 3 inches in length.

Sheets: A total of 24 sheets in Group I and 28 sheets in Group II was tested. Of this number, 8 sheets in Group I and 15 sheets in Group II had indices of less than 25. The most flammable materials consisted of seat foam, acrylic transparencies and various formulations of plasticized PVC/ABS sheets. Omitting seat foam and clear acrylic plastics from consideration, all of the sheets in Group II had indices of less than 50 except for three materials. The lowest indices were usually recorded for the very thin plastic films and also noncombustibles such as glass or asbestos. Outstanding plastics with indices below 10 were aromatic polyamide, polysulfone, polyvinyl dichloride, and the three halogenated plastic elastomers.

Laminates: A total of 12 laminates in Group I and 9 laminates in Group II was tested. Of this number, six laminates in Group I and four laminates in Group II had indices of less than 25. Moreover, all nine laminates in Group II had indices of less than 50. Laminates with the lowest indices consisted of plastic coated aluminum sheets. Other laminates with a low flame-spread index were constructed with either asbestos or aromatic polyamide substrates.

Seat Cushion Assembly: A series of tests on eight different combinations of upholstery fabric, ticking fabric and polyurethane foam comprising various experimental types of seat assemblies was conducted. Flame-spread index numbers, temperature rise, flame propagation and other data are presented at the end of Table III in the appendix. Substantial improvement was achieved in the flame-spread index numbers and decrease in flammability by replacing the more conventional component materials in seat cushion construction with glass/asbestos ticking fabric and flame-retardant foam. The only goal of the tests was to achieve optimum fire resistance. Practicability of the materials for use in passenger seating was of secondary importance.

CONCLUSIONS

Within the scope of the test program and an analysis of the test results, it is concluded that:

1. Test Method 5902 (5903T latest revision) specified in recent amendments to Federal Air Regulations (Part 25) is satisfactory for establishing minimum self-extinguishing requirements. It is particularly useful as a convenient and relatively simple device for effectively screening interior materials.
2. A supplemental test method is needed to establish additional minimum requirements based on a flame-spread index rating system for the heavier composite and assembly materials as these are actually installed in the aircraft cabin.
3. Substantial increase in the fire resistance of materials has been achieved with the development of the new high temperature plastics in addition to advances in the use of flame-retardant additives to the more conventional plastics.
4. Recently developed synthetic fibers now reaching large-scale production make possible upholstery fabric and rug materials that are basically self-extinguishing and thus capable of meeting the more stringent requirements that were recently proposed (Notice of Proposed Rule Making - NPRM 66-26).
5. Char length measurements obtained for materials designated under paragraph 25.853a of the regulations indicate that the 8-inch limit is excessive and that a reduction in char length and the addition of a flame-out time requirement would be more realistic as originally proposed (NPRM 66-26).
6. New types of plastic sheets and laminates are available that are self-extinguishing within a 1-inch char length and a 2-second flame-out time.
7. Flame-retardant types of polyurethane seat foam are available that are self-extinguishing within a 6-inch char length and zero flame-out time.
8. High temperature polymer chemistry has made possible materials with low flame-spread indices and low heat of combustion.
9. Very low flame-spread indices are obtained with composite plastic materials composed in large part of noncombustibles such as metal, glass, or asbestos.
10. Many of the plastic materials exhibit both heavy smoke and acrid odor.

RECOMMENDATIONS

Based on the conclusions reached from the test results, it is recommended that:

1. Self-extinguishing requirements by Test Method 5902 be extended to include materials now exempt and designated as only flame-resistant under paragraph 25.853b of the regulations.
2. Char length requirements be made more stringent by further limiting the maximum allowable char length.
3. Flame-out time requirements in addition to char length limits be specified.
4. Flame-spread index requirements by the Radiant Panel Test Apparatus be adopted in addition to self-extinguishing requirements by Test Method 5902. This is to provide a more severe fire environment needed to rate more adequately the heavier and composite type of materials as used in the interior construction and furnishings of airplanes.
5. New test methods and requirements be developed to limit the maximum allowable smoke and toxic combustion products below hazardous levels.

(3) F - Facing of test sample.
(4) B - Backing of test sample.

(5) 12+ - Plus sign indicates that flame height exceeds limit of measurement which is 12 inches.

FLAMING AND SELF-EXTINGUISHING CHARACTERISTICS OF AIRCRAFT
CABIN INTERIOR MATERIALS by John F. Marcy and Richard Johnson,
Final Report, July 1968, 44 pp., incl. illus., plus 1 Appendix.
(Project No. 510-001-11X, Report No. NA-68-30)
(DS-68-13)

Descriptors

Aircraft Fires
Test Methods
Fire Safety
Smoke
Toxicity

Unclassified Report

A study was made of the burning characteristics of some 140 different materials for the purpose of obtaining technical data and criteria needed to support current efforts to improve existing Federal Air Regulations governing the use of cabin interior materials in aviation. Comparative tests were conducted on two groups of materials one consisting of materials now in use in air transport, and the second materials proposed for future use with superior fire resistance. Measurements were made of ignition time, burn and char lengths, flame-out time, burn rate, heat of combustion, flame-spread index, etc. Two standard laboratory test methods were employed; namely, (1) Federal Standard CCC-T-191b, Test Method 5902, Vertical Burning Apparatus, and (2) Federal Standard 00136b (ASTM E-162), Radiant Panel Apparatus. Results of the tests were analyzed to indicate (over)
