This report is available at the Federal Aviation Administration William J. Hughes Technical Center's Full-Text Technical Reports page: actlibrary.tc.faa.gov in Adobe Acrobat portable document format (PDF).
The Fuel Tank Flammability Assessment Method (FTFAM) is a Federal Aviation Administration-developed computer model designed as a comparative analysis tool to determine airplane fuel tank flammability as a requirement of Title 14 Code of Federal Regulations 25.981. The model uses Monte Carlo statistical methods to generate flammability data for certain unknown variables over known distributions for a large number of flights. The FTFAM iterates through each flight, calculating the flammability exposure time of each flight given the data input provided by the user. Calculating this flammability exposure time for a sufficiently large number of flights results in statistically reliable flammability exposure data. These calculations can be performed by the user for virtually any type of airplane fuel tank (body tank, wing tank, auxiliary tank, etc.) both with and without a flammability reduction method being employed.

This report serves as a user’s manual for this computer model to assist the user in its operation and to discuss the permissible changes that may be made to this model specific to a particular fleet of aircraft. It is updated through version 10 of the FTFAM. The user should reference Advisory Circular 25.981-2A for additional guidance on when to use this model and for a discussion of interpretation of results.

EXECUTIVE SUMMARY

The Fuel Tank Flammability Assessment Method (FTFAM) is a Federal Aviation Administration-developed computer model designed as a comparative analysis tool to determine aircraft fuel tank flammability as a requirement of Title 14 Code of Federal Regulations 25.981. The FTFAM uses Monte Carlo statistical methods to generate flammability data for certain unknown variables over known distributions for a large number of flights. The FTFAM iterates through each flight, calculating the flammability exposure time of each flight given the data input provided by the user. Calculating this flammability exposure time for a sufficiently large number of flights results in statistically reliable flammability exposure data. These calculations can be performed by the user for virtually any type of aircraft fuel tank (body tank, wing tank, auxiliary tank, etc.) both with and without a flammability reduction method being employed.

This report serves as a user’s manual for the FTFAM to assist the user in its operation and to discuss the permissible changes that may be made to this model specific to a particular fleet of aircraft. It is updated through version 10 of the FTFAM. The user should reference Advisory Circular 25.981-2A for additional guidance on when to use this model and interpretation of results.
1. INTRODUCTION.

The Fuel Tank Flammability Assessment Method (FTFAM) is a computer model that is used as a comparative tool to assist in determining the potential flammability exposure of the fuel tank ullage of a fleet of particular aircraft. To accomplish this, the model simulates a large number of flights, comparing the bulk average fuel temperature at each time increment of flight to the lower flammability limit (LFL) and upper flammability limit (UFL). When the bulk average fuel temperature is higher than the LFL and lower than the UFL, the fuel vapor is said to be flammable.

The model uses Monte Carlo statistical methods to determine several unknown variables necessary for the computations. Standardized distributions of these variables, based on Appendix N of Title 14 Code of Federal Regulations Part 25, are used by the model to randomly select a value for each unknown while maintaining accuracy of the actual distribution. These random number methods are used to determine the fuel flashpoint temperature, flight mission length, and ambient and cruise temperatures. By Monte Carlo theory, generating these random numbers over a sufficiently large number of trials will minimize the errors associated with these probabilistic calculations.

It should be noted that this model was written as an engineering tool, and that normal programming conventions have not been followed in its development. Rather, the code of the model was written in such a way that the engineers using it could easily understand and follow the computations and theory involved. This manual serves as a tool for the user to assist in the operation of the model and is updated through version 10 of the FTFAM.

2. MODEL OVERVIEW.

The Monte Carlo method employed in this model uses random number generation techniques over a standardized range of values for several variables. The results of the multivariable problem were calculated over a large number of trials to compute the average result or range of results.

In a broad view of the analysis, as shown in figure 1, the main components to the problem are the environment surrounding the fuel tank, flight mission data, fuel properties, and the thermal characteristics of the tank. Once these four components are determined, whether by user input or by Monte Carlo calculations, the model can then determine whether the ullage of the fuel tank for each time increment of flight is flammable or not; and therefore, the percent of the mission time that the fuel tank is flammable. Performing this over a large number of iterations gives the user a value for the fleet average flammability exposure for a specific aircraft model. A simplified flowchart of the major computations of the model is shown in figure 2. An expanded version of this flowchart, with all user inputs and model preprocessing, is discussed in section 3.1.

Save Flight Info (including flammability and FRM data)

All flights completed

Determine fleet average % Flam & plot results
The user should note that if the aircraft design uses complex fuel transfer features or other features that significantly influence the thermal characteristics between tanks, the model does not have the capability to analyze these effects. The user should refer to Advisory Circular (AC) 25.981-2 for guidance in this case. A qualitative flammability assessment method is acceptable for conventional unheated aluminum wing tanks. Guidance on performing the qualitative flammability assessment and determining if it is appropriate for the fuel tank under evaluation is provided in AC 25.981-2A.

The model was tested using Microsoft Excel 2000®, Microsoft Excel XP®, and Microsoft Excel 2003® on Microsoft Windows 2000® and Microsoft Windows XP® operating systems. Operation on all other versions of Microsoft Excel® and/or Microsoft Windows® is subject to further verification of the model.

2.1 OVERVIEW AND DESCRIPTION OF MODEL WORKSHEETS.

The model consists of several separate worksheets that are used for notation to the user, data input, computation, and presentation of results. The worksheets can be separated into the categories shown in table 1. It should be noted that some worksheets appear in more than one category, as they serve multiple functions. In addition, the user can use several of these worksheets as tools to debug and fix any issues that may arise, such as discrepancies in expected versus actual results. Sections 2.1.1 through 2.1.6 discuss each worksheet and its function in detail.

<table>
<thead>
<tr>
<th>Notation</th>
<th>Data Input</th>

<tbody>
<tr>
<td>Intro</td>
<td>User Inputs and Results FRM</td>
<td>Summary of n Cases Internal Calculations Internal Calc 2 Internal Calc 3 Internal Calc 4</td>
<td>User Inputs and Results FRM Summary of n Cases</td>
</tr>
</tbody>
</table>

In all worksheets, a yellow cell denotes a user input cell. Any cell not shaded yellow must remain untouched by the user unless approved by the Federal Aviation Administration (FAA).

2.1.1 Intro Worksheet.

At first opening the computer model, the user is taken to the Intro worksheet. This worksheet provides a brief statement of the model’s intended purpose as well as several notes and limitations as to its use. On this worksheet, website addresses are provided where the user can find additional information. In addition, contact information for questions or comments regarding the model is provided.
2.1.2 User Inputs and Results Worksheet.

The User Inputs and Results worksheet is the main interface of the FTFAM. It contains all user inputs necessary for performing a Monte Carlo flammability analysis as well as the results from the analysis. The inputs located on this worksheet are divided into six categories, each of which is discussed thoroughly in section 3.1. The results from the Monte Carlo analysis are displayed on this worksheet in the form of a graph depicting the percentage of flight time that the tank was flammable for each of the performed missions.

2.1.3 Flammability Reduction Method Worksheet.

It should be noted that this worksheet is not needed unless a flammability reduction method (FRM) analysis is conducted. The FRM worksheet allows the user to evaluate the effectiveness of an FRM. The effectiveness of an FRM is separated into reliability and performance factors. The results of the FRM analysis are displayed on this page in the form of several different tables, all of which will be discussed in section 3.4.2.

2.1.4 Single-Flight Worksheet.

The Single-Flight worksheet allows the user to simulate and analyze a particular flight scenario. The user can either perform a single-flight scenario by entering flight time and temperature data specific to that flight or by entering a flight number from the Monte Carlo analysis. The results of the single-flight scenario are displayed in two graphical formats on this worksheet. It should be noted that when performing the Monte Carlo analysis, these plots depict the results of the last flight performed.

2.1.5 Summary of n Cases Worksheet.

The Summary of n Cases worksheet displays the results of each flight in tabular format, sorted by the percentage of flight time that the fuel tank was flammable. Along with preflight ground time, flight time, and various flight-specific temperatures, this table also includes the amount of time that the tank was flammable, the amount of time that the FRM was maintaining an inert ullage, and the percentage of total flight time for both.

2.1.6 Internal Calculation Worksheets.

There are four Internal Calculation worksheets in the model that contain all the essential information processed by the model. All data inputs, calculated values, and the results are stored here for use by the program. All pertinent data are then copied to other worksheets to be displayed in a user-friendly fashion. These worksheets are only used by the model and should not be modified by the user in any way. They are provided to the user for troubleshooting purposes only.
3. OPERATION OF THE MODEL

The main interface for general operation of the model is the User Inputs and Results worksheet. This worksheet contains all the input cells and various cells displaying much of the calculated results. Cells in this and all worksheets contained in the model are shaded according to their use. A yellow shaded cell indicates a user input; these are the only cells that should be modified by the user. A light blue shaded cell indicates a computed result, and the green shaded cells located throughout the model are buttons that perform an operation when left-clicked.

3.1 MONTE CARLO ANALYSIS USER INPUTS

Figure 3 shows a flowchart depicting the main computations of the FTFAM, including FRM computations, and the usage of each user input. When the Monte Carlo analysis is being performed without an FRM, there are six user input categories.

- Airplane Data
- Flight Data
- Fuel Tank Usage Data
- Body Tank Input Data
- Fuel Tank Thermal Data
- Multiflight Monte Carlo Data

There are six blocks in the User Inputs and Results worksheet corresponding to these categories, as shown in figure 4. Sections 3.1.1 through 3.1.6 define and discuss each of the parameters within each category.
OAT = Outside air temperature  Tamb = Ambient temperature
AFM = Aircraft Flight Manual  MTBF = Mean time between failure
Tcrz = Cruise temperature  MEL = Minimum Equipment List

OAT = Outside air temperature
AFM = Aircraft Flight Manual
NM = Nautical miles
3.1.1 Airplane Data.

The airplane data that are required to perform the Monte Carlo calculations includes the maximum range of the aircraft, the number of engines, and the outside air temperature (OAT) cutoff limit. These inputs are located in the Airplane Data block on the User Inputs and Results worksheet, as shown in figure 5.

![Airplane Data Block](image)

3.1.1.1 Maximum Range of Aircraft.

The maximum range of the aircraft along with the number of flights to be performed (section 3.1.6.1) is used by the model to develop a mission distribution. Figure 6 shows a sample mission distribution for an aircraft with a maximum range of 4,500 nautical miles (nm) and 100,000 total flights. This distribution data is used by the model to randomly select a mission length for each flight that the model generates, while preserving the accuracy in the overall distribution of flights.

![Mission Distribution](image)
It should be noted that this input value is the maximum range of the aircraft for a normal mission for revenue operation. It is not the absolute maximum range of the aircraft without a payload. This maximum range is also used, along with the cruise Mach number (section 3.1.2.1), to determine the maximum flight time. The flight time is also displayed in the Aircraft Data block of the User Inputs and Results worksheet.

To develop an overall mission profile for a particular flight, pre- and postflight is added ground time to each randomly selected flight time. The preflight ground time is set by the model as 30 minutes for short flights (less than 3 hours), 45 minutes for midlength flights (between 3 and 4 hours), and 90 minutes for long flights (greater than 4 hours). The postflight ground time is set by the model at 30 minutes for all flights. Flights performed by the model are restricted to no less than 15 minutes in duration.

3.1.1.2 Number of Engines.

The model uses the number of engines, along with individual flight mission lengths, to determine the appropriate amount of time for the aircraft to climb to its cruise altitude for each flight. Table 2 shows the amount of time for the aircraft to climb to cruise level that is used by the model based on flight mission length and number of engines. The model then uses this and the cruise altitude to determine the climb rate for each flight.

Table 2. Time to Climb to Cruise Altitude (in Minutes) Based on the Mission Length and Number of Engines

<table>
<thead>
<tr>
<th>Number of Engines</th>
<th>Mission Length (Percent of Absolute Maximum Range)</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>&lt;20%</td>
</tr>
<tr>
<td>2</td>
<td>20</td>
</tr>
<tr>
<td>3</td>
<td>25</td>
</tr>
<tr>
<td>4</td>
<td>25</td>
</tr>
</tbody>
</table>

It should be noted that descent rates, unlike climb rates, are fixed in the model and do not vary based on airplane type. The descent time is calculated by the model using descent rates of 2500 ft/min down to 4000 ft and 500 ft/min from 4000 ft to touchdown.

3.1.1.3 Outside Air Temperature Cutoff Limit.

This cell allows the user to input a temperature cutoff point for the case where the operation of an aircraft is limited to a maximum temperature as specified in the Aircraft Flight Manual (AFM). In any case that the random ambient OAT is above this limit, the model, instead of using the OAT, will use the OAT cutoff limit temperature that was entered by the user. Operating in this manner simulates the aircraft waiting until the OAT cools to within the AFM limits.
If there is no cutoff temperature limit, the user should input into this cell a large number outside the range of ambient temperatures, such as 150°F, so that the OAT cutoff limit will not be activated.

3.1.2 Flight Data.

The flight data that are required to perform the Monte Carlo calculations are the cruise Mach number, altitude steps and tank ram recovery. These inputs are located in the Flight Data block of the User Inputs and Results worksheet, as shown in figure 7.

<table>
<thead>
<tr>
<th>Flight Data</th>
<th>Tank Ram Recovery</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cruise Mach Number</td>

</tr>
<tr>
<td></td>
<td>35000 ft</td>
</tr>
<tr>
<td></td>
<td>39000 ft</td>
</tr>
</tbody>
</table>

P_{total} = Total pressure

Figure 7. Flight Data Block

3.1.2.1 Cruise Mach Number.

The cruise Mach number input is the Mach number at cruise altitude during a typical revenue operation. The Mach number is used by the model to determine each flight profile and flight time.

3.1.2.2 Cruise Altitude Steps.

This set of altitudes define the step cruise levels used by the program. For airplanes that typically do not use a three-step profile, all three values can be set to be equal. The climb between these steps is treated as instantaneous, as opposed to the climb rate used from takeoff to the first cruise level, as discussed in section 3.1.1.2. The way that the model treats the cruise altitude steps is broken into four categories:

- Flight Times Less Than 50 Minutes—The flight time is divided with 40% allocated for climb and 60% for descent. For very short flights, it is possible that the first altitude step will never be reached. Due to the variable climb rates (discussed in section 3.1.1.2), a short amount of cruise time is possible in these flights. In cases where this occurs, the first altitude step is used.

- Flight Times Between 50 and 100 Minutes—The flight cruises at the first altitude step and does not step to the other levels.
- Flight Times Between 100 and 200 Minutes—Two cruise step altitudes are used, with the step increase occurring midway through cruise time.

- Flight Times Over 200 Minutes—Three cruise step altitudes are used, with the cruise time equally split three ways.

For example, if 31-, 35-, and 39-thousand foot altitude steps were entered, possible flight profiles generated for a short, medium-length, and long flights are shown in figure 8. The 30-, 45-, and 90-minute preflight and 30-minute postflight ground times (see section 3.1.1.1) are also included in figure 8.

![Figure 8. Possible Flight Profiles Generated With 31-, 35-, and 39-Thousand Foot Cruise Altitude Steps, Including Pre- and Postflight Times](image)

For flights longer than 2 hours, the model uses a routine to introduce a different ambient temperature for the latter stages of flight and landing to replicate the aircraft flying into a new climate. This is performed by the model by ramping to the new temperature over a 45-minute period starting just after the midway point of the cruise cycle. Once at the new temperature (climate), the flight continues to land with a new ground ambient temperature.
3.1.2.3 Tank Ram Recovery.

The ram recovery of the tank vent can have an effect on flammability exposure. As such, the user may input the tank ram recovery as a percentage of the total ram recovery pressure. If ram recovery is used, the input should be verified by analysis and flight test data.

3.1.3 Fuel Tank Usage Data.

Data concerning fuel tank usage that are required to perform the Monte Carlo calculations are the tank full and empty times and the engine start times. These inputs are located in the Fuel Tank Data block of the User Inputs and Results worksheet, as shown in figure 9.

<table>
<thead>
<tr>
<th>Fuel Tank Usage Data</th>
</tr>
</thead>
<tbody>
<tr>
<td>Tank Full any time before</td>
</tr>
<tr>
<td>Tank empty any time after</td>
</tr>
<tr>
<td>Engines or equipment started at</td>
</tr>
</tbody>
</table>

Figure 9. Fuel Tank Usage Data Block

3.1.3.1 Tank Full and Empty Times.

The model uses the time prior to touchdown that the tank is full and empty to calculate the lapse rate for the fuel temperature. This lapse rate allows the calculation of the fuel temperature at each time step during the flight.

Figure 10 is a graphical representation of the tank full and empty times measured prior to touchdown for each tank type (center wing tank (CWT), auxiliary tank, and main tank with reserves) for a maximum-range flight.
For a CWT that is used first, the tank full time would be the maximum flight time, while the tank empty time would be the time prior to touchdown that the tank becomes empty. Therefore, for shorter flights, the tank would be empty at takeoff.

For an auxiliary tank, which is used next in the flight cycle, the tank will remain full in the early part of long flights; thus, the tank full time is the time prior to touchdown that the fuel starts to be depleted. Similar to the CWT, the tank empty time would be the time prior to touchdown that the tank becomes empty. However, it should be noted that for a main tank with reserves the term empty is defined as the tank’s reserve level, not an actual empty tank. As such, the tank empty time for a main tank with reserves would be 0 minutes prior to touchdown, not the time that the tank runs dry. Similarly, the thermal data (see section 3.1.5) for an empty main tank with reserves would be for a tank at reserve levels, not empty levels.

### 3.1.3.2 Engine Start Time

The program assumes that normal heat loads (e.g., environmental control systems) are operating from the start of the flight. The engine start time cell gives the option to simulate a fuel tank with additional heat input from engines and/or systems. For example, some airplanes have hydraulic heat exchangers, engine oil and fuel recirculation features, or other systems that add heat to the tank.
The input value for this cell is the time prior to takeoff that the engines and/or systems start adding heat to the tank. This value will vary by airplane utilization. For example, longer-range airplanes typically have much longer times, where the engines and/or systems function on the ground. The change in actual thermal effects from operating these engines and/or systems is entered in as a difference in thermal time constants from when the systems are inoperable (see section 3.1.5.2).

3.1.4 Body Tank Input Data.

The body tank data needed for the model consists of five inputs that allow the user to study tanks that are completely enclosed in the fuselage, or a similar container, with no direct cooling to ambient air. It allows the calculated temperatures of the fuel tank to be controlled by the temperature of the compartment in which it is contained. In addition, the tank may be set to be pressurized in flight, or vented to ambient pressure based on the design of the tank. It should be noted that if the tank of interest is not a body tank, all five input cells should be set to zero. These inputs are located in the Body Tank Input Data block within the User Inputs and Results worksheet, as shown in figure 11.

<table>
<thead>
<tr>
<th>Body Tank Input Data</th>
<th>Set all values to zero if tank is not a body tank.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Tank in the fuselage with no cooling from outside air</td>
<td>0 1=Yes, 0=No</td>
</tr>
<tr>
<td>Tank pressurized in flight</td>
<td>0 1=Yes, 0=No</td>
</tr>
<tr>
<td>Pressure differential relative to ambient</td>
<td>0 psi</td>
</tr>
<tr>
<td>Tank is pressurized in flight</td>
<td>0 minutes before takeoff</td>
</tr>
<tr>
<td>Temperature of compartment surrounding tank</td>
<td>0 Deg F</td>
</tr>
</tbody>
</table>

Figure 11. Body Tank Input Data Block

The first input asks the user if the tank of interest is located in the fuselage with no direct cooling from ambient air (i.e., if it is a body tank). The user should enter the numeral 1 here if it is a body tank, and 0 if it is not. Next, the user must indicate if the tank is pressurized in-flight. Again, the user should enter the numeral 1 if it is, 0 if it is not. If 0 is entered in this cell, the tank pressure will then be set to the altitude of the airplane at each time step.

If the tank is pressurized in-flight, the user must then enter the pressure differential, relative to ambient pressure, that the tank is pressurized to. The user must also input the time prior to takeoff at which the tank pressurization system becomes active. These inputs should be established based on validated values, because the pressure altitude of the tank will vary based on tank vent designs and will have a significant effect on flammability.

The final piece of required body tank information is the temperature of the compartment surrounding the tank. At the start of the flight (i.e., time = 0), the fuel tank temperature is set to ambient to represent the fuel loaded from the ground supply. The fuel will then cool (or heat) to the surrounding compartment temperature using the exponential time constants for ground conditions discussed in section 3.1.5.2.
3.1.5 Fuel Tank Thermal Data.

The fuel tank thermal data required to perform the Monte Carlo calculations are the temperature differential to both the ambient and total air temperature (TAT) as well as a number of exponential time constants.

The model assumes that the fuel is loaded at the start of the mission (i.e., time = 0). The time constants required are then used to determine the manner in which the fuel will heat or cool in response to its surroundings. These time constants are inputted for a near empty and a near full tank, both on the ground and in-flight. In addition, for ground conditions, these values must be entered with and without the engines running. The tank thermal data is critical to achieving accurate results with the FTFAM, and as such, all inputs must be validated through flight test data or a thorough thermal analysis.

These inputs are located in the Fuel Tank Thermal Data block within the User Inputs and Results worksheet, as shown in figure 12.

![Figure 12. Fuel Tank Thermal Data Block](image)

3.1.5.1 Temperature Differential Relative to Ambient and TAT.

The Equilibrium DeltaTemp input cell is the fuel temperature differential relative to ambient temperature that will be reached given sufficient time. This value must be determined from a thermodynamic analysis of the tank and the surrounding systems. In addition, this value must be entered with and without the engines and/or systems running to better represent the heat input to the fuel tank from the engines or other equipment.

Similarly, for flight conditions, the user must input the fuel temperature differential relative to the TAT that will be reached given sufficient time. If the tank is in the fuselage with no cooling from outside air, then this input would be relative to the surrounding compartment temperature.
It is assumed that the flight thermal data entered includes heat input from the engines and systems.

3.1.5.2 Exponential Time Constants.

There are six exponential time constants required as input, which define how the fuel in the tank heats or cools in response to heat input:

- Ground condition, tank near empty, engines off
- Ground condition, tank near empty, engines on
- Ground condition, tank near full, engines off
- Ground condition, tank near full, engines on
- In-flight condition, tank near empty
- In-flight condition, tank near full

The fuel is assumed to heat or cool according to a normal exponential transition as shown in equation 1, where \( t \) is the time constant at the current time step and \( T_{\text{final}} \) is the long term equilibrium fuel temperature (discussed in section 3.1.5.1). Additionally, the model assumes a linear change in time constants as fuel is burned and the tank moves from a full to empty state.

\[
\frac{T_{\text{fuel},i} - T_{\text{fuel},i-1}}{T_{\text{final}} - T_{\text{fuel},i-1}} = 1 - e^{-t/\tau}
\]  

(1)

All time constants must be determined either by flight test or by a thermodynamic analysis backed up by flight tests. If, based on this data, this exponential transition does not satisfactorily model the fuel’s temperature change, the user does have the ability to modify the model’s code to allow for a more accurate representation of the fuel’s temperature profile. This and other allowable code modifications are discussed in section 4.

3.1.6 Multiflight Monte Carlo Data.

The required data specific to the multiflight Monte Carlo analysis are the number of flights to be performed, whether or not the user would like to freeze the random numbers generated by the Monte Carlo analysis for developmental purposes, and whether or not the user would like to perform an analysis of flights operating on warm days only. These inputs are located in the Multiflight Monte Carlo Data Block within the User Inputs and Results worksheet, as shown in figure 13.

<table>
<thead>
<tr>
<th>Multi-Flight Monte Carlo: Number of Flights</th>
<th>Freeze random numbers</th>
<th>Warm day analysis only</th>
</tr>
</thead>
<tbody>
<tr>
<td>Number of Flights</td>
<td>0</td>
<td>0</td>
</tr>
</tbody>
</table>

1 = yes, 0 = no

Figure 13. Multiflight Monte Carlo Data Block
3.1.6.1 Number of Flights.

Due to the nature of the Monte Carlo analysis, the model’s accuracy is increased as the number of flights is increased. As such, in order for the Monte Carlo analysis to be valid for showing compliance with flammability requirements, a minimum number of flights must be performed to ensure the applicable flammability limits are met. Table 3 shows the minimum number of flights and the maximum acceptable levels to meet requirements for 3% and 7% flammability exposure requirements (as set forth in the FRM Notice of Proposed Rulemaking).

Once the number of flights to perform has been determined and it, along with all other inputs, has been entered in the User Inputs and Results worksheet, the Run Monte Carlo button should be pressed to initiate the Monte Carlo analysis. Viewing and interpreting these results will be discussed in section 3.4.

Table 3. Minimum Number of Flights and Acceptable Level Necessary to Meet Flammability Requirements

<table>
<thead>

<td>2.98</td>
<td>6.96</td>
</tr>
<tr>
<td>1,000,000</td>
<td>3.00</td>
<td>7.00</td>
</tr>
</tbody>
</table>

3.1.6.2 Random Number Freeze.

As an option, for development purposes, the user can freeze the random numbers generated by the model by entering a 1 in this input box. This will force the model to use the same set of random numbers during each set of analyses, allowing the user to vary input parameters to better understand their sensitivity effect on the flammability exposure of the fuel tank. This option must be turned off, by entering a 0 in the input box, for final certification analysis.

3.1.6.3 Warm-Day Analysis.

As an additional option, the user has the ability to perform a warm-day flammability analysis. By entering a 1 in this input box, the model will analyze only those flights for which the ground ambient temperatures are above 80°F. This allows the user to further analyze the flammability exposure of a particular fuel tank under what would be considered warm-day operations.

3.2 MONTE CARLO ANALYSIS OPERATION WHEN A FLAMMABILITY REDUCTION METHOD IS USED.

When a Monte Carlo analysis is being performed, and an FRM is being used, the user must enter some additional inputs. The effectiveness of an FRM is broken into two parts: (1) the reliability effect of the FRM and (2) the performance effect of the FRM.
Reliability effects of an FRM are determined from analyses of potential malfunctions of the FRM, which would make the system ineffective. To determine these effects, the user must input the following pieces of data into the FRM worksheet in addition to all inputs previously discussed:

- **Mean Time Between Failure (MTBF)**—This is the number of hours that the FRM is expected to be operational between failure events.

- **Failure Detection Capability**—The input needed here is the expected number of flights that it will take before the FRM system failure is detected. This value depends on system monitoring and information display as well as operational procedures such as frequency of FRM maintenance checks.

- **Minimum Equipment List (MEL) Assumption**—The value entered here is the average expected time, in-flight hours, that it will take for the FRM system to be restored once a failure has been detected.

The values used for these three inputs must be shown to be accurate by analysis and testing of the FRM and are entered as inputs on the FRM worksheet.

The user should note that once an FRM evaluation has been performed (cases run), the reliability inputs can be changed, and the results will be displayed without needing to perform the FRM evaluation again.

The performance effects of an FRM relate to the FRM’s ability to maintain a nonflammable ullage while operating as expected. The program, as written, contains code to replicate the use of a generic ground-based inerting system. The user must replace this code with programming based on the exact FRM system intended to be used. Performance of the system under all flight conditions must be taken into account in writing this portion of the code and must be shown to be accurate by analyzing and testing the FRM. Further details concerning writing and inserting this code are discussed in section 4.3.

Once the performance aspect of the FRM has been coded and inserted into the model, the user must enter all FRM reliability data and the data values discussed in section 3.1. Once this data is entered fully, the user presses the Run FRM Evaluation button on the FRM worksheet to initiate the FRM analysis. It should be noted that pressing the Run Monte Carlo button on the User Inputs and Results worksheet will perform only a flammability analysis (i.e., with no FRM) regardless of the inputs made on the FRM worksheet.

### 3.3 SINGLE-FLIGHT USER INPUTS

Located in the Single-flight Condition block of the User Inputs and Results worksheet is a set of values that allow the user to input a specific set of conditions for a single flight and examine the results. This could be useful in a troubleshooting operation, as well as looking at various trends, and the effects of changing certain variables. The Single-Flight Condition block is shown in figure 14.
All inputs needed for the Monte Carlo analysis (discussed in sections 3.1.1 through 3.1.6.2) are still necessary, except for the number of flights. In addition to these inputs, the user must enter in this data block information specific to the single flight being performed. The needed inputs are the total flight time, ambient temperature (on the ground and at cruise), and the fuel’s flashpoint. Once these inputs have been entered, the Run Single Flight button can be pressed to initiate the flight analysis. It should be noted that if the user should enter a takeoff ambient temperature that is above the OAT limit, the model will use the OAT limit as the ambient temperature and a warning will display to alert the user of this condition.

As an option, rather than inputting these data for a single flight, the user may also want to run a selected flight from the Monte Carlo analysis to view its results in detail. This can be done by entering the selected case number from the Monte Carlo analysis (found in the Summary of n Cases worksheet under column M) in the block shown in figure 15 and pressing the corresponding Run Selected Flight button.

### Viewing and Interpreting Results

Viewing and interpreting the results of these individual flights, as well as the Monte Carlo analysis results, is discussed in detail in section 3.4.

#### 3.4 Viewing and Interpreting Results

Upon completion of either the Monte Carlo analysis or a single-flight analysis, the model will bring the user to the corresponding results page. For a Monte Carlo analysis, it will be the Summary of n Cases worksheet, and for a single-flight analysis it will be the Result Plots worksheet.
3.4.1 Monte Carlo Flammability Analysis.

The Summary of n Cases worksheet contains the results of the Monte Carlo analysis in a tabular format with a graphical representation of the data displayed in the User Inputs and Results worksheet.

The table on the Summary of n Cases worksheet contains all the vital information for each flight simulated and sorts them by the percentage of flight time that they were flammable in decreasing order. Data given in this table includes the following, as calculated by the Monte Carlo model: (1) preflight ground time, (2) flight time, (3) ambient temperature, (4) cruise temperature, (5) fuel flashpoint temperature, (6) the amount of time the flight was flammable, (7) the percentage of flight time that the flight was flammable, and (8) whether or not the FRM was achieving a nonflammable ullage at each time increment.

A sample of the results is shown figure 16. This graph depicts the percentage of flight time that the tank was flammable for each flight performed in the Monte Carlo analysis, sorted in decreasing order. Also displayed on this graph is a summation of the total percentage of flammable flight time for all flights, termed the Fleet Average Flammability Exposure Percentage. This value is the amount of time the tank was determined to be flammable divided by the total flight time amongst all the performed flights, which is the most important number in determining the flammability exposure of a given fuel tank.

![Fleet Average Flammability Exposure](image)

Figure 16. Summary of Multiflight Monte Carlo Analysis Results

It should be noted that for Monte Carlo analyses consisting of greater than 5000 flights, both the table of all flights on the Summary of n Cases worksheet and the results graph on the User Inputs and Results worksheet will appear blank, because Microsoft Excel cannot save all the necessary data.

Directly beneath this graph, the Monte Carlo analysis results are further broken down in the Warm-Day Operations Results table, as shown in figure 17. This table displays the results for all flights during which the ambient ground temperature before takeoff was greater than 80°F. The
Table shows the total flight time, total time during which the fuel tank was flammable, and the resulting flammability exposure percentage for all flights during warm days (i.e., ambient temperature greater than 80°F). In addition, this table displays the corresponding data for each phase of flight (i.e., ground, climb, each of the three cruise levels, descent, and taxi-in.) The table in figure 17, in this instance, shows the fuel tank was flammable for 72.7% of the time during warm day operations.

Figure 17. Warm-Day Operations Results Table

If the user, after evaluating the results on this worksheet, would like to further evaluate the data from a particular flight contained in the Monte Carlo analysis table, the flight case number can be entered and performed as a single-flight scenario, as discussed in section 3.3.

3.4.2 Monte Carlo With FRM Analysis.

The results from an FRM analysis are displayed in the FRM worksheet in several different tables. The first of these, shown in figure 18, displays the baseline flammability data (i.e., with no FRM) and the corresponding flammability data due to reliability failures of the FRM. Values for both of these are shown for the fleetwide average and for the climb and cruise portions of flight for those flights where ground ambient conditions were greater than 80°F.

Figure 18. The FRM Table Displaying Baseline and Reliability Effects Data
There are two larger tables below this table that allow the user to analyze the performance effect of the FRM, as shown in figure 19. Both tables display flammability data for each phase of flight (i.e., ground, climb, each cruise altitude, descent, and taxi-in) as well as the total time of flight. Data are again presented for the fleetwide average and for flights where ground ambient conditions were greater than 80°F.

</table>

Figure 19. The FRM Table Summarizing Performance Effects on Each Phase of Flight

The last table, as shown in figure 20, provides the user with a summary of the FRM effectiveness. It includes the percentage of flammable time due to reliability factors as well as performance factors and the total fleet effectiveness due to the FRM. It also includes the total flammable percentage times (due to both reliability and performance factors) for ground and climb times during flights where ground ambient conditions were greater than 80°F.

Figure 20. The FRM Table Displaying FRM Effectiveness
In addition to this data, the baseline Monte Carlo results (i.e., with no FRM) are displayed in the Summary of n Cases and User Inputs and Results worksheets, as discussed in section 3.4.1.

3.4.3 Single-Flight Flammability Analysis.

The results from a single-flight analysis are shown on the Single-Flight worksheet in two different graphical formats, time- and altitude-based plots.

The time-based plot, as shown in figure 21, depicts the TAT, fuel temperature, LFL temperature, and UFL temperature as a function of time. In addition, along the secondary y axis, the red bar indicates the percent flammability exposure time for that particular flight. This percent flammability number is also displayed in the User Inputs and Results worksheet in the Single-flight Condition block. The points on this plot where the bulk average fuel temperature falls between the LFL and UFL temperatures are the portions of the flight when the tank was flammable. The points where the bulk average fuel temperature falls below the LFL temperature are the portions of the flight when the tank was lean. Although no points are shown in figure 20, if the fuel temperature was above the UFL temperature, it would indicate that the tank was too rich. The TAT is also displayed in this plot for reference to the outside ambient conditions of the airplane.

The altitude-based plot on this worksheet, shown in figure 22, displays the same information, but in terms of altitude. Again, points where the bulk average fuel temperature falls between the LFL and UFL temperatures are the portions of the flight that the tank was determined to be flammable. Similarly, the points to the left of the LFL temperature indicate that the tank was lean, and points to the right of the UFL temperature indicate that the tank was rich. Some small amount of perturbation from a smooth curve is evident in this figure due to rounding of temperatures to every 1000 ft.
Figure 21. Single-Flight Results—Time-Based Plot

Figure 22. Single-Flight Results—Altitude-Based Plot
4. PERMISSIBLE USER MODIFICATION OF THE CODE.

Although the Monte Carlo model is a very effective and versatile tool, there are certain aspects of the model’s code that may need to be modified by the user based on acquired aircraft data. The permissible code changes within the model include how the model computes the tank thermal effects, fuel tank usage, and FRM performance effects. Anything outside these computations must not be modified in any way. To adhere to the FAA standards, any changes must be sufficiently documented and validated with flight test data or analysis backed up by flight data.

4.1 FUEL TANK THERMAL EFFECTS.

The thermal behavior of the fuel tank due to its surroundings, as discussed in section 3.1.5, is based on calculations using the fuel temperature differential relative to the ambient temperature and TAT as well as several exponential time constants. If flight test data or a detailed analysis of the fuel tank’s thermal behavior shows that this method cannot yield an accurate representation of the actual fuel tank’s fuel temperature profile, then modification of the code is warranted.

4.2 FUEL TANK USAGE.

The usage of fuel within the tank is calculated at each time increment by the Monte Carlo model using a linear decay from the tank full to tank empty times, as discussed in section 3.1.3.1. Figure 10 displayed this type of fuel usage and is repeated here for reference as figure 23. This representation of a fuel tank’s usage is meant as a general profile for a generic tank. Depending on the aircraft and fuel tank configuration, such as shifting fuel between tanks, actual fuel usage may be very different from this.

In this situation, the user is able to modify this portion of the code to better represent the actual fuel tank usage. Changes to this portion of the code must be shown, either by flight test data or a detailed analysis of the tank’s usage of fuel backed up by data, to provide an accurate representation of fuel usage by the tank in question.
4.3 USING A FLAMMABILITY REDUCTION METHOD.

When an FRM is being evaluated during a Monte Carlo flammability analysis, it is necessary for the user to ensure that the code of the model reflects any performance effects of the FRM. The performance effects of an FRM relate to the FRM’s ability to maintain a nonflammable ullage while operating as expected and should be programmed separately from the reliability effects—those due to the FRM being inoperative due to a system or part failure. The program, as written, contains code to replicate the use of a generic ground-based inerting system. The user must replace this with code based on the exact FRM system intended to be used.

Performance of the system under all flight conditions must be taken into account in writing this portion of the code and must be shown to be accurate by analyzing and testing the FRM. If the FRM module needs additional data beyond what is provided by the Monte Carlo model, the user is required to compute that information and also show it to be accurate by analysis and/or testing.

The output of the added FRM module should be the parameter FRMyesno, which is set to 0 at each time increment when the FRM is not maintaining the tank from being flammable and is set to 1 at each time increment when it is sustaining a nonflammable ullage.

The placement of this FRM module is clearly identified in the model’s code with a comment statement which reads TEST FRM ONLY. The code that follows this comment statement is the current default FRM performance code that replicates the use of a generic ground-based inerting
system. This code must be replaced with the user’s own code reflecting the specific FRM in use. This section of the code is shown below for reference, beginning with the comment statement:

```
'================================TEST FRM ONLY================================
'This is a very simple FRM to test the FRM module and data collecting code. The FRM is
'assumed to be effective after t=10 min and to be effective until the end of cruise for all flights.
If FRMonoff = 0 Then
  flamyesnoFRM = flammyesno
  GoTo 299
End If
If time1 < phase6 And time1 > 10 Then
  FRMyesno = 1
End If
```

When using a nitrogen inerting system as the FRM, it is necessary to take into account oxygen evolution, the release of oxygen from the fuel, when performing a flammability analysis.

Air evolution in fuel is driven by how much air is dissolved in the fuel, what keeps it dissolved, and what drives it out. Air dissolves in fuel until the partial pressure of the dissolved air equals the local partial pressure of the ullage. There is an Ostwald Coefficient that defines the amount of gas the fuel can absorb to reach equilibrium, which varies with temperature. Once the gas is dissolved in the fuel, it will remain dissolved until the ullage partial pressure is changed, with surface tension of the fuel helping to keep the gas in solution. This leads to a condition of supersaturation where the partial pressure of the dissolved gas can be significantly higher than the ullage partial pressure. This can result in a condition where a triggering mechanism can break the surface tension effect, causing a large amount of gas to be liberated quickly.

The problem is approached by determining the partial pressure of oxygen in both the ullage and the fuel, assuming total saturation of the fuel at the beginning of the flight. It is then assumed that the oxygen release, or absorption, is driven by the difference of the two partial pressures and that there is some exponential mass transfer time constant to reach equilibrium. An effect for supersaturation, where the concentration of oxygen has not reached equilibrium with that of the ullage, can also be added by keeping the gas dissolved in the fuel (i.e., maintaining 100% saturation) until a certain pressure differential is achieved.

The user should replicate this effect by assuming 100% saturation at normal atmospheric conditions at refueling (i.e., the fuel is saturated with air at 21% O₂ and has not been prescrubbed of O₂). Under quiescent conditions, with no altitude changes, the time constant used for gas transfer is 3500 minutes. For climb conditions, no mass transfer takes place until above 15,000 ft, and during the remainder of climb the time constant used is 100 minutes.
5. DOCUMENTATION AND VALIDATION OF CODE MODIFICATIONS.

All modifications to the model’s code must be thoroughly documented and validated both through detailed analysis and flight test data. The modified code must be shown to provide an accurate representation of the aircraft’s systems and their interaction with the environment. Guidance for documenting and validating fuel tank thermal models is provided in Appendix 1 of AC 25.981-2A. Similar documentation and validation is required for all other code modifications.
